Introduction
Trophoblastic cells of the placenta comprise cytotrophoblasts, spongiosiotrophoblasts, trophoblastic giant cells in the labyrinthine zone, and spongiotrophoblasts, trophoblastic giant cells in the junctional zone. The latter constitute the interhemal membrane or placental barrier. Anaemia causes adverse fetal outcome. This poor outcome has been attributed to degenerative changes in the placenta which include reduction in size, placental infarcts, syncytial knots, decreased vascularity and fibrinoid necrosis. Trophoblastic cells are important in the function of the placenta and are sensitive to placental insult. Accordingly, knowledge of the effects of various insults is important in mitigating adverse fetal outcome. Studies on the anaemia induced ultrastructural changes in the placental trophoblastic cells are, however, scarce, but nonetheless important in elucidating the basis for poor fetal outcome. This study therefore investigated the effects of anaemia on the ultrastructure of placental trophoblastic cells.

Materials and Methods
This experimental study was carried out on forty-nine female Sprague-Dawley rats. The animals were derived from a generation of clones over a 19 year period and divided into control and experimental groups. The study was approved by the ethical committee in the University of Nairobi and implemented in accordance with international policies and directives governing the use of animals in experiments. These directives were formulated to secure best environment and care for animals. Basic principles in
Chronic anaemia causes degenerative changes in trophoblast cells of the rat placenta

Animal care were applied in this study which included the following: using less invasive techniques, optimum living conditions and medical care, causing no pain or distress, not performing unnecessary tests, reducing the number of animals tested to the minimum. Rats were handled with care, without rushing to avoid frightening the animals.

Chronic anaemia was induced by withdrawing 1.5 ml of blood on five alternate days, through the retrobulbar plexus according to the protocol by Markovic et al. (2009). Anaemia was diagnosed when the haemoglobin level dropped below 12 g/dl. The mean haemoglobin level for the control rats was 13.1 g/dl; ranging from 12.88 g/dl on day 17 to 13.4 g/dl on day 21. In anaemia on the other hand, haemoglobin was consistently below 12 g/dl range from 10.98 g/dl on day 17 to 11.44 on day 21. The difference was statistically significant on all gestational dates. Chronic anaemic rats had mean values of haemoglobin concentration that are significantly less than those of the control mean values in all studied groups (Table 1).

Rats were anaesthetised by ether inhalation, the abdomen was opened using a midline incision, the uterus was exposed and placentas were extracted on days 17, 19 and 21 (Table 2). All placentas were cut in two equal parts. Half was processed for light microscopy and the other processed for transmission electron microscopy.

For light microscopy, the placentas were cut into 5 mm³ pieces, fixed in 10% buffered formaldehyde solution, dehydrated in alcohol, cleared in xylene and embedded in paraffin wax. Five micron sections were cut, deparaffinized, stained with Hematoxylin and Eosin and examined at various magnifications in control and anaemic rats using a Leica ICC 50 microscope (Leica Microsystems, Wetzlar Germany). Photographs were taken using a high resolution digital camera attached to a computer.

For transmission electron microscopy, 1 mm³ tissue blocks of placenta were fixed in 2.5% phosphate buffered glutaraldehyde for two hours at 4°C. They were then washed in 0.1 M phosphate buffer 4×20 min and then for 24 hours again at 4°C. Secondary fixation was done in 2% osmium tetroxide in 0.1 M phosphate buffer, pH 7.4 for 1 hr at room temperature. This was then followed by washing in double distilled water 4×20 min at room temperature. Dehydration was done in ascending grades of ethanol, cleared in propylene oxide and embedded in epon resin. Semithin sections were cut at approximately 500–1000 nm thickness and stained with toluidine blue. Ultrathin sections were stained with uranyl acetate counter stained with lead citrate and then examined under JEOL transmission electron microscope at various magnifications using the protocols of Hunter and Bozzola and Russel. Images were taken by high resolution camera.

Results

The trophoblastic cells in the placenta of control animals showed clear margins, cytoplasm, nuclei with distinct chromatin and nucleoli. Microvilli on the cerrytrophoblasts were definite, long and numerous. Those in placenta of anemic animals, on the other hand, showed features of degeneration. The nucleus of the trophoblastic cells in the interhemal membrane showed features of chromatolysis such that the chromatin material appeared to have disappeared from the nucleus, leaving a naked nucleolus. The cell margins became indistinct. This was in contrast to the controls in which cells appeared distinct with clear margins, nuclei and prominent chromatin and nucleoli (Figures 1a and b). The cells in the interhemal membrane displayed numerous dark bodies, vacuolation, disorganization, as well as degeneration of the endothelial lining with thickening of the basement membrane (BM) (Figures 1c and d).

The syncytiotrophoblasts showed chromatin and nucleolar degeneration, cytoplasmic and nuclear vacuolation (Figures 2a and b). Cytotrophoblasts developed marked nuclear vacuolation and dark bodies. The surfaces facing the MBS bore microvilli which were reduced in number and the cells had different orientations on the surface of the cytrophoblast (Figures 2c and d).
Giant trophoblastic cells in control animals showed clear margins, granular cytoplasm, and prominent homogeneous nucleus with prominent nucleolus. In anaemia on the other hand, the giant trophoblastic cells lost cell margins, the cytoplasm and nucleus developed vacuoles, as the nucleolus disappeared (Figures 3 and b).

**Figure 1.** Electromicrographs of placental labyrinth in control and chronic anemic rat placenta at gestational day 21. (a) Electromicrograph of placental labyrinth in control rats showing normal maternal blood spaces (MBS), fetal capillaries (FC) with red blood cells (RBCs) and a number of giant cells with clear cell margins and prominent nucleoli (arrows) (×1200). (b) Electromicrograph of labyrinth in anaemic rats showing dilated MBS, fewer fetal capillary (FC), decreased numbers of giant cells and anisocytosis. Note the absence of clear cellular and nuclear margins of numerous dark bodies (×1200). (c) Electromicrograph of labyrinth of control animals showing FC with well-defined endothelial lining (E) and nuclei with 2 nucleoli. Note also the regular interhemal membrane (IHM) (×3000). (d) Electromicrograph of labyrinth in anaemic rats showing abnormal shape and size of RBCs in FC, disorganization of E of FC and disruption of its wall, more dark bodies (arrows) and disorganized IHM (×3000).
Chronic anaemia causes degenerative changes in trophoblast cells of the rat placenta

The number giant trophoblastic cells in the anaemic group was relatively less compared to the controls (Figures 4a and b).

Discussion
The cells most affected by anaemia were syncytiotrophoblasts, cytotrophoblasts and trophoblastic giant cells. Syncytiotrophoblasts and cytotrophoblasts showed changes characterized by nuclear and cytoplasmic vacuolation. Similar degenerative changes in these cells have been reported in hypoxia,[17,18] pre-eclampsia[19] and hypertensive disease of pregnancy.[20] The changes are concordant with reports that these cells are sensitive to factors which cause placental injury.[13,21,22] Many of them, especially those related to hypoxia occur due to placental apoptosis consequent to oxidative stress.[21] The syncytiotrophoblast is actively involved in the transport of metabolites to and from the embryo/fetus; production of hormones, growth factors and receptors which regulate maternal metabolism and placental development.[11,24] Accordingly, the changes observed are likely to adversely impact on placental function by decreasing transfer and synthetic activity[16] and hence contribute to poor fetal outcome. In addition, cytotrophoblastic cells...
showed abnormal orientation, reduction in size and density of microvilli. The decreased microvillus density observed in the current study has also been reported in other complications such as IUGR placentae[25] and pre-eclampsia.[17] In the rat, cytotrophoblasts continuously differentiate into ST during villous formation and development and are important in invasion of blood vessels remodeling in early stages of implantation.[26] Their degeneration may undermine placenta function, and contribute to poor outcome.

The trophoblastic giant cells secrete steroid hormones and prolactin related cytokines, to work on preparation and adaptation of the maternal body systems to pregnancy to ensure that proper placentation occurs.[12,27,28] In the current study, these cells showed marked cytoplasmic and nuclear vacuolation. Similar degenerative changes have been reported in diabetes and hyperthermia,[29,30] and placental chemical toxicity,[31–33] and gestational protein restriction.[34] They are probably genetically programmed. Indeed it has been reported

Figure 3. Photomicrographs of giant trophoblastic cells in rat placenta. (a) Giant cell in control at gestational day 17, showing normal homogeneous granular cytoplasm, uniform nucleus with prominent nucleolus. (b) Giant cell in anemia at gestational day 17 showing irregular cell margins, nuclear degeneration, cytoplasmic and nuclear vacuolation (arrows) (Hematoxylin and Eosin, x1000). N: nucleus; n: nucleolus. [Color figure can be viewed in the online issue, which is available at www.anatomy.org.tr]

Figure 4. Photomicrograph of labyrinth and junctional zones in placenta of control rats at gestational day 19. (a) Giant trophoblastic cells in the control rat placenta showing normal distribution and appearance. Note the distinct dark nuclei (N) with definite nucleoli (n). (b) Giant cells in the anaemic group showing relative reduction in their number compared to the control. Note the nuclei (N) are lighter stained the nucleoli (n) are less distinct of giant cells. Hematoxylin and Eosin, x100. [Color figure can be viewed in the online issue, which is available at www.anatomy.org.tr]
that O₂ levels regulate cell fate through hypoxia induced factor-1 (HIF-1) which activates genes involved in cellular response to O₂ deprivation. These morphological changes may alter placental function and embryo nutrition, and contribute to the poor fetal outcome.

Conclusion
Chronic anaemia causes trophoblastic cell degeneration. This may undermine the functional integrity of the cells and constitute part of the mechanism for poor fetal outcome.
